ACKNOWLEDGMENTS

I acknowledge with gratitude the help and continual guidance I received from my adviser, Professor Robert B. McGhee. I am especially grateful to him for his invaluable assistance in the initiation and development of this problem. I am also grateful to Professor Kenneth J. Breeding for his helpful suggestions and a careful review of this work.

I wish to thank Professor B. Chandrasekaran for his course on pattern recognition which was of considerable help to me. I also wish to thank the Dept. of Computer and Information Science at The Ohio State University for the use of their computer facilities.

I am indebted to Messrs. R. Parthasarthy and Jeram Advani for their invaluable help. Thanks are also due to Ethel-Marie LeVasseur for doing an excellent job of typing the manuscript.

This research was supported by The United States Air Force Office of Scientific Research under Grant AFOSR-71-2048.

CHAPTER I

INTRODUCTION

The realization of machine recognition of pictorial data has long been a challenging goal, but has seldom been attempted with anything more complex than alphabetic characters. In this thesis the task of recognition of three dimensional objects from their optical images is considered from the view of identifying and estimating the translation and rotation of the object with respect to a given reference frame.

The approach presented here makes use of the theory of twodimensional moment invariants for planar geometric figures developed
by Ming-kue Hu [1]. Complete systems of moment invariants under translation, similitude and orthogonal transformations are derived. By
carefully utilizing these properties, a sample set is constructed in
which each sample is represented by a vector which characterizes the
image for a certain orientation of some object from the given group.
A pattern recognition technique is then described in which a parametric
representation of the input signal is employed. The decision process
using typical samples partitions the space into regions that envelop
the chosen samples of a class. A simulation program based on the above
outline is successfully developed which not only identifies objects,
but also determines their orientation and position in space.

In this research three different objects, a F-4B PHANTOM II, a MIRAGE III C, and a MIG 21 aircraft, were considered. The models of these aircraft of scale 1: 72 are mathematically represented by a "wire model" structure [2] by considering a finite number of points, called nodes, on the body of the model. These nodes are interconnected to approximate the curved and planar surfaces on the body of the aircraft by a number of straight lines. A simulation program is used to generate the computational model of the silhouette of the aircraft for any position and orientation in space. Certain invariant properties of these images, as mentioned earlier, are used for the construction of the sample sets. Different amounts of noise were added to the points on the boundary of the simulated image to learn about the performance of this method when using unfocused, hazy or unclear optical images.

Besides the identification of aircraft, this approach can also be used for various other problems. A television camera onboard a docking space craft can take a picture of a docking target and thus after estimating translation and rotation, the docking craft can position itself for automatic docking. In addition, this approach can help in developing a robot eye for use on automatic assembly lines in industries.

A review of different pattern recognition techniques related to this research appears in Chapter II. The problem formulation along with a complete set of invariant moments is presented in Chapter III.

In Chapter IV, the computational results including the effect of noise

on parameter estimation are given. Conclusions, a summary of the results, and future research areas are discussed in Chapter V. Finally, Appendix I presents documentation of computer programs at the end of the thesis.

CHAPTER II

SURVEY OF PREVIOUS WORK

2.1 Introduction

detail."

Munson [3] describes the pattern recognition process in terms of the following three stages where each is considered as an independent component:

TRANSDUCER + PREPROCESSOR - CLASSIFIER.

However, considering the first step, "it is doubtful if recognition occurs before the eyes are directed toward a (known) object, since otherwise we would not bother to look at the object" [4]. Thus it would seem reasonable to use the raw data in the form of the image as bulk memory and allow the transducer to search for "regions of interest" [5]. In considering the three stages, the literature overwhelmingly concentrates on the various aspects of classification. It is here that a substantial objection can be raised. Is not the more significant part of the problem that of characterizing the world by a set of properties that provide the desired discrimination? In fact Selfridge [6] defines pattern recognition solely in terms of "the extraction of significant features from a background of irrelevant

Kazmierczak and Steinbuch [7] state that "the human visual system

is capable of selecting features or criteria from a pattern where the statement of the description would be independent of registration, skew, size, contrast, deformation, or other noise effects." What is needed according to Duda [8] are "rugged features". "A rugged feature is one whose presence is not changed, and whose characteristics are not greatly altered, by normal variations in the image of a character in a given category." It is emphasized, and this is an important point, that no general theory exists to allow us to choose what features are relevant for a particular problem. With these comments in mind, the object of the rest of the chapter is to present a discussion of a few computer methods and algorithms used in conjunction with image analysis.

2.2 Contour Tracing

One of the approaches to reduce the amount of data in a picture involves scanning a picture and tracing a contour or outline of the figure and then basing the recognition or classification decision on this information [9]. It is well known [10], that "contours carry a denificant fraction of the information required for recognition of image objects." Examples of this approach applied to character recognition are discussed in the literature [11] - [13].

Hemami, McGhee and Cardner [14] in their paper presented an algorithm which uses the information contained in the boundary of the pattern by successively reading the coordinates of the boundary and developing a nonlinear regression analysis technique for simultaneous estimation of rotation and translation of the image objects. One of

the advantages of using a contour description is that the latter is independent of shape, translation, size and rotation [15].

2.3 Conic Section Approximation

Here we consider shape description in terms of conic sections.

An individual pattern is defined as a non-negative function, f, on the real plane, subject to certain constraints on position, size, orientation, etc. In a given frame of reference any conic section may be uniquely represented as

$$O(x,y) = ax^{2} + 2hxy + by^{2} + 2gx + 2fy + c = 0, (2-1)$$

where $a^2 + 4h^2 + b^2 + 4g^2 + 4f^2 + c = 1$ and the first non zero element of the vector (a, 2h, b, 2g, 2f, c) is positive. Such a vector will be referred to as a conic vector.

The true Euclidian distance from a point (u,v) to the nearest point on the conic Q(x,y) = 0 is a troublesome quantity to evaluate, and we use instead the quantity |Q(uv)|, which vanishes on and only on the conic and, loosely speaking, takes larger values for points (u,v) further from the conic. The weighted squared discrepancy between the pattern, P, and the conic may then be defined as

$$D = \iint P(u,v) |Q(uv)|^2 du dv, \qquad (2-2)$$

and the "best" conic is that for which D is the least. This problem may be formulated as an eigen value problem of order six, the conic

vector corresponding to the smallest root defining the best conic [16].

The best conic approximation has been used by Paton [16] as a discriminator in chromosome analysis. An example of a best conic approximation to a certain chromosome pattern is shown in Fig. 2.1.

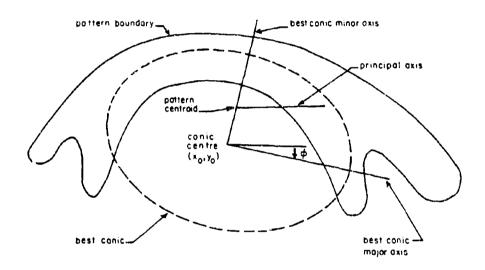

Figure 2.1 Line Drawing of a Chromosome Pattern and its Best Conic Approximation

2.4 Shape Descriptors

Intuitively, it is preferable to describe an object using gross

properties rather than local or neighborhood descriptors. Shape description is undoubtedly one of the most important aspects of pattern recognition. It is desirable in many applications to describe the structure of an object independently of orientation, translation or even some types of distortion. Interesting discussions regarding recognition of shape and their computer models can be found in papers of Blum [17], [18].

Based on some shape description theories, an interesting shape descriptor referred to as a medial axis transformation (MAT) was developed by Blum [18]. He describes the generating model which is used to define MAT: "Consider a continuous isotropic plane that has the following properties at each point: 1) excitation - each point can have a value of 0 or 1, 2) propagation - each excited point excites an adjacent point with a delay proportional to the distance, and 3) refractory or dead time - once fixed, an excited point is not affected by a second firing for some arbitrary interval of time. A visual stimulus from which the contours or edges have been extracted impinges on such a plane at some fixed time and excites the plane at those points. This excitation spreads uniformly in all directions but in such a way that the waves generated do not flow through each point."

The MAT is then defined as the locus of the corners in the wave-front. The (propagating) contours have been likened to the front of a grassfire ignited on the pattern boundary and the MAT is then the locus of points where the fire is extinguished. Several examples of MATs are shown in Fig. 2.2. Note that, if the MAT turns out to be a

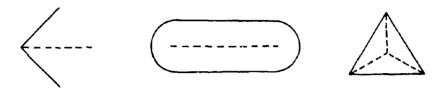

Figure 2.2 Examples of MAT Transformation

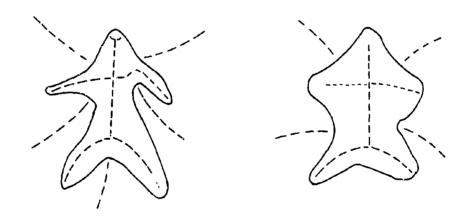

Figure 2.3 The MAT for Both a Simple Sketch and a Distorted Version of a Man

straight line, then the shape of the object under consideration is symmetrical. The gross properties of the transformation are obviously related to the macroscopic and structural properties of the pattern. This is demonstrated by Blum [18] using both a sketch-like representation of a human and its distorted version as shown in Figure 2.3. The basic properties of the MAT remain unchanged.

2.5 Moment Transformations

A set of two-dimensional moment invariants have been found by Hu [1]. Based upon these moment invariants, a pattern-recognition theory has been formulated which considers two patterns to be similar if they differ at most in the following respects:

- (A) Location
- (B) Size
- (C) Orientation

With the help of moment transformations, we can find a pattern function as a number m = F(P) associated with each pattern, P, which is

- (a) invariant under (A) to (C), i.e., if patterns P_1 and P_2 are similar according to (A) to (C) then $F(P_1) = F(P_2)$;
- (b) characteristic of dissimilar patterns, i.e., if patterns P_1 and P_2 are not similar according to (A) to (C) then $F(P_1) \neq F(P_2)$;
 - (c) easy to compute.

If such a function cannot be found, then one might try to use several functions $F_1(P)$, $F_2(P)$, ..., which satisfy (a) and (c), though not (b), in the hope that for any given pair P_1 and P_2 of dissimilar patterns, at least one of the functions $F_1(P)$ would give $F_1(P_1) \neq F_1(P_2)$.

The latter is the approach we propose to follow.

2.5.1 Definition of Two Dimensional Moments

Let there be N points equally distributed along the boundary of a certain pattern as shown in Figure 2.4.

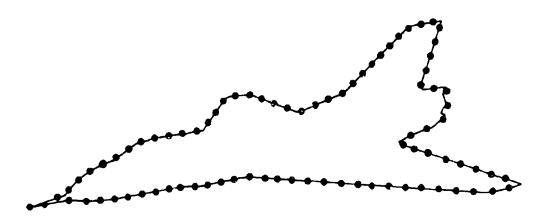

Figure 2.4 Discrete Representation of the Boundary of a Pattern

Let the coordinates of these points be (x_1,y_1) , (x_2,y_2) , ..., (x_N,y_N) . Then the two dimensional $(p+q)^{th}$ order moments are defined as

$$m_{pq} = \frac{1}{N} \sum_{i=1}^{N} x_i^p y_i^q$$
, $p + q = 0,1,2,...$ (2-3)

Also let $(\overline{x}, \overline{y})$ be the centroid of the given pattern. Then,

$$N \cdot \overline{x} = \sum_{i=1}^{N} x_i$$

or

$$\bar{x} = \frac{1}{N} \sum_{i=1}^{N} x_i = m_{10}$$
 (2-4)

Similarly

$$\overline{y} = m_{01} . \qquad (2-5)$$

2.5.2 Central Moments

The central moments are defined as

$$u_{pq} = \frac{1}{N} \sum_{i=1}^{N} (x - \overline{x})^{p} (y - \overline{y})^{q}$$
 (2-6)

where

$$\bar{x} = m_{10}$$
 , $\bar{y} = m_{01}$. (2-7)

It should be noted that $u_{01} = u_{10} = 0$. Now, let us consider the effect of translation on these central moments. Let

$$x_i^{\dagger} = x_i + \alpha \tag{2-8}$$

$$y_i' = y_i + \beta \tag{2-9}$$

where α , β are constants. Then,

$$m_{10}' = \frac{1}{N} \sum_{i=1}^{N} x_i'$$

$$= \frac{1}{N} \sum_{i=1}^{N} x_i + \frac{N \cdot \alpha}{N}$$

$$= m_{10} + \alpha$$
 (2-10)

or

$$\overline{x}' = \overline{x} + \alpha . \qquad (2-11)$$

Similarly

$$\overline{y}' \approx \overline{y} + \beta$$
 (2-12)

Using this new centroid of the pattern, let us now calculate the new central moments under translation.

$$u_{pq}' = \frac{1}{N} \sum_{i=1}^{N} (x_i' - \overline{x}')^p (y_i' - \overline{y}')^q$$

$$= \frac{1}{N} \sum_{i=1}^{N} (x_i + \alpha - \overline{x} - \alpha)^p (y_i + \beta - \overline{y} - \beta)^q$$

$$= u_{-n} \qquad (2-13)$$

Thus the central moments are invariant under translation.

I

1

From Eq. (2-6) it is quite easy to express central moments in terms of ordinary moments. For the first three orders,

$$u_{00} = m_{00} = 1$$
 (2-14)

$$u_{01} = u_{10} = 0$$
 (2-15)

$$u_{20} = u_{20} - (u_{10})^2$$
 (2-16)

$$u_{02} = m_{02} - (m_{01})^2$$
 (2-17)

$$u_{30} = m_{30} - 3m_{20}m_{10} + 2(m_{10})^3$$
 (2-18)

$$u_{21} = m_{21} - m_{20}m_{01} - 2m_{11}m_{10} + 2(m_{10})^2m_{01}$$
 (2-19)

$$u_{12} = w_{12} - w_{02} = 0 - 2w_{11} = 0 + 2(w_{01})^2 = 10$$
 (2-20)

$$u_{03} = m_{03} - 2m_{11}m_{01} + 2(m_{01})^2$$
 (2-21)

From here on, for simplicity of description, all moments referred to are central moments and u_{pq} will be simply expressed as:

$$u_{pq} = \frac{1}{N} \sum_{i=1}^{N} x_i^p y_i^q$$
 (2-22)

2.5.3 Similitude Moment Invariants

Under a similitude transformation, i.e., change of size, we have

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} \gamma & 0 \\ 0 & \gamma \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix}, \gamma = constant (2-23)$$

Let us now calculate the new central moments \mathbf{u}_{pq}^{\prime} after the transformation.

$$u_{pq}^{\prime} = \frac{1}{N} \sum_{i=1}^{N} x_{i}^{p} y_{i}^{q}$$

$$= \frac{1}{N} \sum_{i=1}^{N} \gamma^{p} x_{i}^{p} \gamma^{q} y_{i}^{q}$$

$$= \gamma^{p+q} \frac{1}{N} \sum_{i=1}^{N} x_{i}^{p} y_{i}^{q}$$
(2-24)

or

$$u_{pq}^{1} = \gamma^{p+q} u_{pq}$$
 (2-25)

Therefore we have the following absolute similitude moment invariants:

$$\frac{u_{pq}'}{\gamma^{p+q}} = u_{pq}$$
, $p + q = 2, 3, ...$ (2-26)

Using similitude invariants of central moments, pattern identification can easily be accomplished independently of translation and size.

2.5.4 Orientation Moment Invariants

Under the orthogonal transformation of rotation,

$$x^1 = x \cos \theta - y \sin \theta$$
, (2-27)

$$y' = x \sin \theta + y \cos \theta . \qquad (2-28)$$

Thus, the new moments under rotation will be as follows:

$$u_{pq}' = \frac{1}{N} \sum_{i=1}^{N} x^{ip} y^{iq}$$

$$= \frac{1}{N} \sum_{i=1}^{N} (x \cos \theta - y \sin \theta)^{p} (x \sin \theta + y \cos \theta)^{q}$$

$$(2-29)$$

$$u_{pq} = \frac{1}{N} \sum_{i=1}^{N} x^{p} y^{q}$$

$$(2-30)$$

It can be shown [1] that the three second order moments satisfy the following relations:

$$2u_{11}' = (u_{20} - u_{02}) \sin 2\theta + 2u_{11}\cos 2\theta$$
 , (2-31)

$$u_{20}' + u_{02}' = u_{20} + u_{02}$$
, (2-32)

$$(u_{20}' - u_{02}')^2 + 4(u_{11}')^2 = (u_{20} - u_{02})^2 + 4u_{11}^2$$
. (2-33)

There are two ways of using Eqs. (2-31), (2-32) and (2-33) to accomplish pattern identification independently of orientation:

(...) The method of principal axes: if the angle θ is determined from the equation (2-31) to make $u_{11}^{-1}=0$, then we have,

$$\tan 2\theta = -2u_{11}/(u_{20} - u_{02}).$$
 (2-34)

The x^* , y^* axes determined by any particular value of θ satisfying Eq. (2-34) are called principal axes of the pattern. With added restriction, such as $u_{20}^{-1} > u_{02}^{-1}$ and $u_{30}^{-1} > 0$, θ can be determined uniquely. Moments determined with respect to such a pair of principal axes one independent of orientation.

(B) The method of orthogonal moment invariants: the two relations Eqs. (2-32) and (2-33) are invariant under rotation, and they can be used directly for orientation-independent pattern identification. Let these two invariant relations be called M₁ and M₂ respectively. The discrimination property user also be increased by including higher-order moment invariants. For third-order moments, we can show that the following four expressions are invariant under orthogonal transformation.

$$M_3 = (u_{30} - 3u_{12})^2 + (3u_{21} - u_{03})^2$$
 (2-35)

$$M_4 = (u_{30} + u_{12})^2 + (u_{21} + u_{03})^2$$
 (2-36)

$$M_5 = (u_{30} - 3u_{12}) (u_{30} + u_{12}) [(u_{30} + u_{12})^2 - 3(u_{21} + u_{03})^2]$$
+ $(3u_{21} - u_{03}) (u_{21} + u_{03}) \cdot [3(u_{30} + u_{12})^2 - (u_{21} + u_{03})^2]$
(2-37)

$$M_{6} = (u_{20} - u_{02}) \{(u_{30} + u_{12})^{2} - (u_{21} + u_{03})^{2}\}$$

$$+ 4u_{11} (u_{30} + u_{12}) (u_{21} + u_{03})$$
(2-38)

Similarly, higher-order orthogonal moment invariants can be derived. In fact, it has been found that there exists a complete system of infinitely many such invariants [1].

It is interesting to note that in the above methods, because of complete orientation independence property, different patterns which could be obtained from each other by just proper rotation, such as '6' or '9' can not be distinguished. If the given pattern is of circular or n-fold rotational symmetry, then the determination of θ by Eq. (2-34) breaks down. This is due to the fact that both numerator and denominator are zero for such patterns.

2.6 Sample Set Construction and Linear Separatibility

Based on the features extracted from the optical image or the pattern, one can form a sample set which characterizes classes from a small number of their members. In addition to this, pattern recognition techniques must perform a basic function of recognizing a new input

stimulus and classify it as a member of one of several classes.

Machine learning, the automatic accomplishment of classification, requires partitioning the vector space into regions so that each region should contain mostly members of a single class. The regions so constructed characterize the classes. The block diagram shown in Figure 2.5 illustrates a general pattern recognition system that exhibits the functions discussed above [19]. The parameter extractor is used to

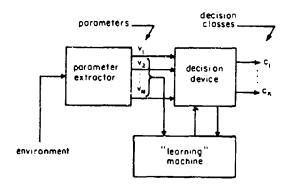

Figure 2.5 General Pattern Recognition System

represent the machine's environment as a vector in an N-dimensional vector space. Machine learning is employed to determine, from sample inputs, the best method of partitioning the space into different decision regions, and the decision device, which implements the regions designed through machine learning, evaluates new input stimuli and classifies them according to the region in which they are contained.

Most of the machines used are linear, employing only linear

discriminants, i.e., correlations with stored reference vectors or comparisons of weighted combinations of the parameters. Hyperplanes are used to partition the space of measurable input parameters to separate members of one stimulus class from those of another. Combinations of these linear techniques with logical rules, can construct boundaries to quite complex distributions. In many practical problems the classes are not linearly separable (not separable by hyperplanes) and their members are not contained in disjointed simply-connected regions of space of observable parameters. In these cases, better decision rules than those provided by linear discriminants should be used to minimize the probability of decision errors [19]. This is illustrated in Figure 2.6 where members of different classes are contained in regions labeled A and B. These classes are linearly separable in Figure 2.6a but not in the more complex distribution shown in Figure 2.6b.

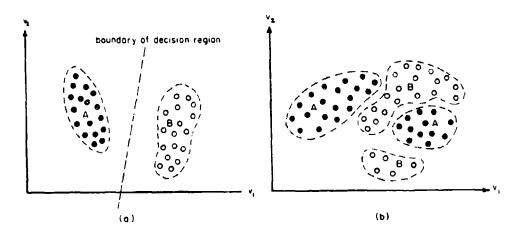

Figure 2.6 Different Distributions of Two Classes

2.7 Recognition of Three-Dimensional Objects

The schemes developed by many authors for the recognition of a solid object from its optical image require the perspective transformation of a three-dimensional field, with hidden lines removed.

The perspective projection is used to fit the given picture. The computer oriented techniques of forming perspective projection of a given object are presented by Weiss [20], Comba [21] and Loutrel [22].

Guzman [23] and Winston [24] in their work in the field of recognition of three dimensional objects developed a scheme which recognizes the objects irrespective of their translations and rotations. They consider a three-dimensional structure composed of bricks, wedges and other simple objects. It is assumed in their work that a preprocessing of some sort has taken place, and the picture to be analyzed is available in a symbolic format of points, lines and surfaces. The recognition scheme identifies the object from its picture by selecting a combination of surfaces and relating it to an object.

The only two pattern recognition schemes in the literature, to the author's knowledge, which deal with the estimation of three translations and three rotations associated with the object, are developed by Roberts [25] and Advani [26]. Roberts [25] in his work assumes that the objects seen could be constructed out of some familiar parts, called the models. The procedure starts by first converting the picture into a line diagram; then the points in the line diagram which fit a transformation of some model are found. This model has a set of topological equivalent points. Finally the mean-square error

minimization technique with some threshold is used to eliminate models which fit the picture topologically, but do not fit exactly without being deformed. This scheme does not yield the depth information but relies on a support theorem for the purpose of estimating the depth or the translation along the optical axis of the camera. This theorem requires the object in the scene to be supported by the ground or another object resting on the ground. This is one of the disadvantages in Roberts' recognition algorithm.

Advani [26] developed an algorithm to estimate the three translations and three rotations of an object from its silhouette by the use of regression analysis. Advani, in his work, synthesizes the silhouette for r certain translation and rotation, and then tries to match this synthesized silhouette with the given cilhouette of the object with unknown translation and rotation. Advani's method is fairly accurate, even in the presence of large amounts of noise, but the main drawback of this algorithm is that it takes a much longer time for recognition than what would be needed in many practical applications. A new technique for recognition of three dimensional objects is developed in this research which has the potential of reaching real time identification.

CHAPTER III

PROBLEM FORMULATION

3.1 Introduction

The problem which concerns us may be stated as follows: a digital computer receives an optical image of a three-dimensional object, and on the basis of this information it has to identify the object and estimate its position and orientation in space.

It is assumed here that it is possible to obtain the silhouette of the picture through some type of preprocessing of the optical image [5]. On this silhouette a number of equally spaced data points are generated and used for the calculation of moments. Using these moments, as mentioned earlier, the computer should assign the image to a certain object, and estimate the six parameters to be defined later in section 3.4.

3.2 Transformation of the Real World

The first assumption here is that the picture is a view of the real world recorded by a camera or other comparable device and therefore that the image is a perspective transformation of a three-dimensional field. This transformation is a projection of each point in the viewing space, toward a focal point, onto a plane. The transformation depends on the camera used, the enlargement printing process,

and, of course, the coordinate system the real world is referred to. Let us fix the real world coordinates X, Y and Z by assuming that the focal plane is the Y = -2f plane, that the focal point is at X = 0, Y = -f, Z = 0, and the optical axis is colinear with the Y axis. In order that the picture not be a reflection, we choose the focal plane in front of the camera. Thus the focal plane is really the plane of the print, not of the negative. Let U and V represent the coordinates on the focal plane of the projections for the points in the real world. This arrangement is shown in Figure 3.1.

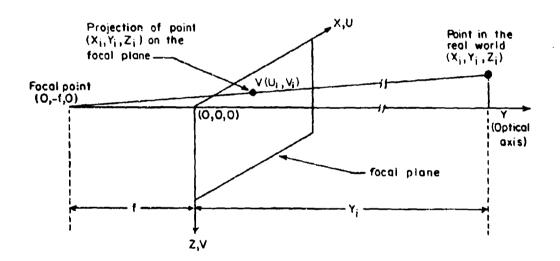

Figure 3.1 Camera Transformation

Let (X_1, Y_1, Z_1) be a point in the viewing space and (U_1, V_1) be its projection on the focal plane as shown in Figure 3.1 This

transformation is shown below:

$$u_1 = \frac{f}{Y_1 + f} \cdot x_1$$
, (3-1)

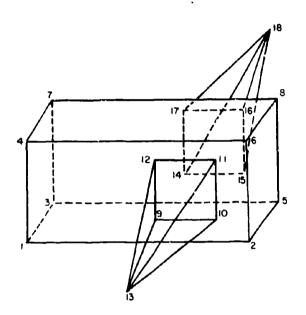

$$V_{\underline{i}} = \frac{f}{Y_{\underline{i}} + f} \cdot z_{\underline{i}} \qquad (3-2)$$

where, f, is the focal length of the camera.

3.3 Mathematical Representation of Three-Dimensional Objects with the Wire Frame Structure

The mathematical representation of the three-dimensional object is achieved by selecting s number of points, depending on the complexity of the structure, on the body of the prototype model of a given scale. These points are referred to as nodes. These nodes are then appropriately interconnected to approximate the planar and curved surfaces on the body of the object by a number of straight lines. This results in a so called "wire-frame" structure [2], because the straight lines could be considered as wires connected between the fixed points (nodes) which form the frame. The connections between different nodes can be mathematically expressed by a connection matrix in which each row represents a certain node, and therefore the connection matrix has the same number of rows as the nodes selected to construct the wire-frame structure. The different column entries for each row in the matrix show the nodes connected to the one represented by the row. The trailing zeroes in a row show that no more nodes are connected to the

node represented by the row. One such example appears in Figure 3.2. It is to be noted here that the nth row of the connection matrix, represents the nth node of the object, shown in Figure 3.2.

Figure 3.2 Wire Frame Structure and Connection Matrix for a Winged Parallelepiped

3.4 Transformation Matrix

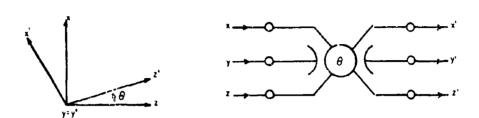

Let us fix a new coordinate system, xyz, to the center of gravity of the object to be identified. The coordinates of the nodes, selected

on the body of the prototype of the object for the wire frame structure representation, are measured with respect to this xyz coordinate system. Let the M nodes, selected for a certain object to be identified, have the coordinates $\{(x_i, y_i, z_i), i = 1, 2, ..., M\}$. At first, let the three axes x, y and z of the coordinate system fixed to the object be colinear with the respective axes, X, Y and Z of the real world coordinates. This is shown by the transformation given below in Eq. (3-3), which relates the coordinates x_i , y_i and z_i of a node to the real world coordinates X_i , Y_i and Z_i .

$$\begin{bmatrix} x_i \\ y_i \\ z_i \end{bmatrix} = \begin{bmatrix} x_i \\ y_i \\ z_i \end{bmatrix} \quad i = 1, 2, \dots, M. \quad (3-3)$$

The relative orientation of two arbitrary orthogonal systems can be specified by a set of no fewer than three angles, usually called Euler angles. Although the concept of the Euler angles is universally used in several applications, there is no agreement on the definition of the Euler angles. There are a large number of possible choices for the three angles required to define an Euler set of angles [27]. A particular set of Euler angles is selected here with the aim of obtaining moment invariance with one of the angles of the set. The transformations for the set of Euler angles selected are shown in Figures 3.3 through 3.6. The symbolic representation used in these figures to accomplish coordinate transformations is straightforward and is

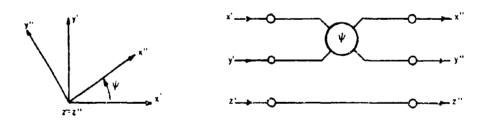

discussed in [28]. The three Euler angles θ , ψ and ϕ are called the elevation, azimuth and roll angles respectively.

$$x^{t} = -z \sin \theta + x \cos \theta$$

$$z' = z \cos \theta + x \sin \theta$$

Figure 3.3 Elevation Angle Transformation

$$x'' = x' \cos \psi + y' \sin \psi$$

$$y'' = -x' \sin \psi + y' \cos \psi$$

Figure 3.4 Azimuth Angle Transformation

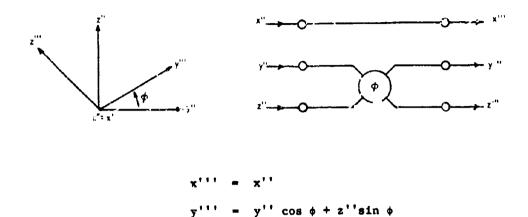

Figure 3.5 Roll Angle Transformation

-y'' sin \(+ z'' \) cos \(\psi \)

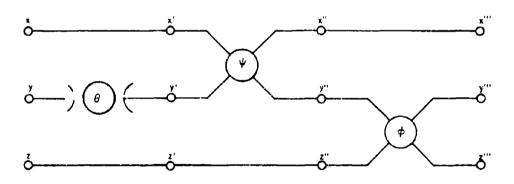

Figure 3.6 Symbolic Representation of the Euler Angle Sequence

The transformation matrix, which relates the coordinates of a node with respect to the two different systems defined earlier, is

as shown below:

$$\begin{bmatrix} \mathbf{x_i} \\ \mathbf{y_i} \\ \mathbf{z_i} \end{bmatrix} = \begin{bmatrix} \cos\theta & 0 & \sin\theta \\ 0 & 1 & 0 \\ -\sin\theta & 0 & \cos\theta \end{bmatrix} \begin{bmatrix} \cos\psi & -\sin\psi & 0 \\ \sin\psi & \cos\psi & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\phi & -\sin\phi \\ 0 & \sin\phi & \cos\phi \end{bmatrix} \begin{bmatrix} \mathbf{x_i} \\ \mathbf{y_i} \\ \mathbf{z_i} \end{bmatrix}$$

$$for i = 1, 2, ..., M \qquad (3-4)$$

After giving the above orientation to the xyz system, let us translate the origin of this system to a point (A, B, C) with respect to the real world coordinate system. The modified transformation is given below:

$$\begin{bmatrix} X_{i} \\ Y_{i} \\ Z_{i} \end{bmatrix} = \begin{bmatrix} \cos\theta & \cos\psi & -\cos\theta & \sin\psi & \cos\phi & \cos\theta & \sin\psi & \sin\phi \\ & + & \sin\theta & \sin\phi & + & \sin\theta & \cos\phi \\ & -\cos\psi & \sin\phi & -\cos\psi & \sin\phi \\ & + & \cos\theta & \sin\phi & -\sin\theta & \sin\psi & \sin\phi \\ & + & \cos\theta & \sin\phi & + & \cos\theta & \cos\phi \end{bmatrix} \begin{bmatrix} x_{i} \\ y_{i} \\ z_{i} \end{bmatrix} + \begin{bmatrix} A \\ B \\ C \end{bmatrix}$$

With the use of this transformation matrix, each node of the wire frame structure can be represented in the XYZ coordinate system, given the three translational and the three rotational parameters.

The projection of these M nodes can be obtained on the image plane and used to construct the computational model of the silhouette [26]. This method of simulating the silhouette for a given set of six parameters is used later for the sample set construction.

3.5 Moment Invariance with Angle of Elevation

It will be shown here that the silhouettes obtained for different values of the elevation angle, with the other parameters remaining the same, are similar in size and shape but differ only in rotation. Therefore the moment invariant functions derived in section 2.5.4 characterize this silhouette for the other given parameters.

It will be assumed that the optical axis of the camera is directed to pass through the center of gravity of the object to be identified, and thus the parameters A and C, defined earlier, will take smaller values compared to the distance of the object along the optical axis. This can be accomplished by using some kind of feedback system which will change the direction of the optical axis so as to bring the centroid of the silhouette to the origin of the UV coordinate system.

The projection of a certain point in the viewing space onto the focal plane is given by the following transformation

$$v_1 = \frac{f}{f + Y_1} \cdot x_1$$
, (3-6)

$$v_i = \frac{f}{f + Y_i} \cdot z_i$$
, (3-7)

where (U_1, V_1) are the coordinates of the projected point in the focal plane. With the assumption that the parameters A and C are small in Eq. (3-5), we have the following relations:

$$Y_i = (\sin\psi)x_i + (\cos\psi\cos\phi)y_i + (-\cos\psi\sin\phi)z_i + B \qquad (3-8)$$

$$X_i = \cos\theta(\cos\psi)x_i + (-\cos\theta \sin\psi \cos\phi + \sin\theta \sin\phi)y_i + (\cos\theta \sin\psi \sin\phi + \sin\theta \cos\phi)z_i$$
 (3-9)

$$2_{i} = -\sin\theta(\cos\psi)x_{i} + (\sin\theta \sin\psi \cos\phi + \cos\theta \sin\phi)y_{i} + (-\sin\theta \sin\psi \sin\phi + \cos\theta \cos\phi)z_{i}$$
(3-10)

It is interesting to note here that Y_i is not a function of the elevation angle θ and hence remains the same for all values of θ , given the parameters ψ , ϕ and B. Thus the factor $K = f/(f + Y_i)$ in Eqs. (3-6) and (3-7) remains constant with θ , for the given values of ψ , ϕ and B. Therefore we have

$$U_{i} = K X_{i}$$
 , (3-11)

$$V_i = K Y_i$$
 , (3-12)

where K is a constant. It can further be shown that the expression $(K_1^2 + Z_1^2)$ is also not a function of the elevation angle θ , given the assumption A = C = 0. Using Eqs. (3-9) and (3-10), we have

$$x_1^2 + z_1^2 = \cos^2 \psi x_1^2 + (\sin^2 \psi \cos^2 \phi + \sin^2 \phi) y_1^2 + (\cos^2 \phi + \sin^2 \psi) z_1^2$$
 (3-13)

Therefore, using this result along with Eqs. (3-11) and (3-12), we have

$$U_1^2 + V_1^2 = K^2(X_1^2 + Z_1)^2$$

= $f(\psi, \phi, B)$ (3-14)

This shows that when the elevation angle of a certain object is changed, the locus of the projection of each node of the object onto the focal plane is a circle with the center as the origin. Thus we can in effect say that the result of varying the elevation angle of a certain object, on its silhouette, is just its rotation in the focal plane, with no change in size and shape. Perspective projections with different elevation angles, but with the same azimuth angle, roll angle and distance along optical axis, appear in Figure 3.7. The moment functions M_1 , M_2 , M_3 , M_4 , M_5 and M_6 derived earlier in section 2.5.4 are therefore invariant with the elevation angle θ .

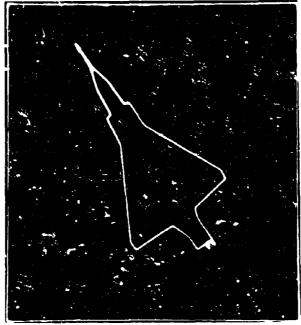

.

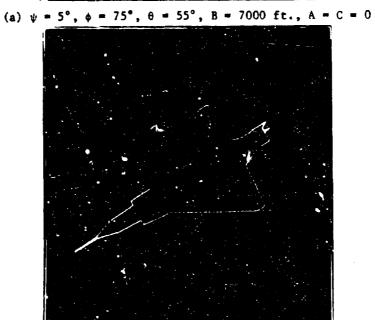

$$M_1 = u_{20} + u_{02}$$
 (3-15)

$$M_2 = (u_{20} - u_{02})^2 + 4u_{11}^2$$
 (3-16)

$$M_3 = (u_{30} - 3u_{12})^2 + (3u_{21} - u_{03})^2$$
 (3-17)

$$M_4 = (u_{30} + u_{12})^2 + (u_{21} + u_{03})^2$$
 (3-18)

(b) $\psi = 5^{\circ}$, $\phi = 75^{\circ}$, $\theta = -30^{\circ}$, B = 7000 ft., A = C = 0

Figure 3.7 Perspective Projections for Different Elevation Angles

$$M_5 = (u_{30} - 3u_{12}) (u_{30} + u_{21}) [(u_{30} + u_{12})^2 - 3(u_{21} + u_{03})^2]$$

$$+ (3u_{21} - u_{03}) (u_{21} + u_{03}) \cdot [3(u_{30} + u_{12})^2 - (u_{21} + u_{03})^2]$$
(3-19)

$$M_6 = (u_{20} - u_{02}) [(u_{30} + u_{12})^2 - (u_{21} + u_{03})^2]$$

$$+ 4u_{11}(u_{30} + u_{12}) (u_{21} + u_{03})$$
(3-20)

3.6 Moment Invariance with Distance along Optical Axis

It is clear that as an object is moved along the optical axis, the first order effect on the image is just a change in size. The second order effect is that a few small portions of the image may appear or disappear when the object is moved along the optical axis. This second order effect diminishes as the distance of the object from the camera increases.

The radius of gyration, r, of a planar pattern is defined as follows:

$$r = (u_{20} + u_{02})^{\frac{1}{2}}$$
 (3-21)

The radius of gyration is directly proportional to the size of the image or inversely proportional to the distance of the object along the optical axis. The size of the image here is defined as the minimum radius of a circle required to enclose the given image completely

with its center at the centroid of the image. Thus the product RK of the radius of gyration of the image and the distance along the optical axis of the object is a constant.

$$RK = (u_{20} + u_{02})^{\frac{1}{2}} \cdot B$$
 (3-22)

Therefore the radius of gyration, r, should be used to normalize the moment functions of Eqs. (3-15) through (3-20) to obtain the similitude moment invariance. Using the results derived in section 2.5.3 concerning similitude moment invariants, we have the following moment functions invariant with the elevation angle θ and the distance B along the optical axis:

$$M_2' = \frac{1}{r^4} [(u_{20} - u_{02})^2 + 4u_{11}^2]$$
 (3-23)

$$M_3' = \frac{1}{r^6} [(u_{30} - 3u_{12})^2 + (3u_{12} - u_{03})^2]$$
 (3-24)

$$M_4' = \frac{1}{r^6} \{(u_{30} + u_{12})^2 + (u_{21} + u_{03})^2\}$$
 (3-25)

$$M_5' = \frac{1}{r^{12}} [(u_{30} - 3u_{12}) (u_{30} + u_{21}) \{ (u_{30} + u_{12})^2 - 3(u_{21} + u_{03})^2 \}$$

$$+ (3u_{21} - u_{03}) (u_{21}^2 + u_{03}) \{ 3(u_{30} + u_{12})^2 - (u_{21} + v_{03})^2 \}]$$
(3-26)

$$M_6' = \frac{1}{r^8} \left[(u_{20} - u_{02}) \left\{ (u_{30} + u_{12})^2 - (u_{21} + u_{03})^2 \right\} + 4u_{11}(u_{30} + u_{12}) (u_{21} + u_{03}) \right]$$
(3-27)

3.7 Elevation Bias Error

Let us consider a silhouette of an aircraft for a certain orientation as shown in Figure 3.8. Let this pattern have a principal axis as shown in the figure. This principal axis is the same as the perspective projection of the x axis of the coordinate system fixed to the center of gravity of the object or the aircraft in the present case. Therefore the inclination of this principal axis of the pattern with the U axis in the projection plane is the elevation angle θ . The positive direction of θ is shown in the figure.

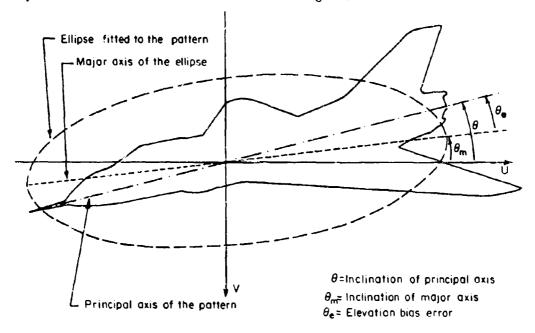

Figure 3.8 Elevation Bias Error for a Pattern

E.

The inclination θ_m of the major axis of the ellipse fitted to the pattern can be found from Eq. (2-34), as shown below

$$\tan 2\theta_m = -2u_{11}/(u_{20} - u_{02})$$
 (3-28)

with added restriction, such as $u_{20}' > u_{02}'$ and $u_{30}' > 0$, θ_m can be determined uniquely from Eq. (3-28).

The elevation bias error, θ_e , for a pattern as seen from Figure 3.8, is defined as the difference between the elevation angle θ and the inclination θ_m of the major axis of the ellipse fitted to the pattern.

$$\theta_{m} = \theta - \theta_{m} \tag{3-29}$$

It is interesting to note here again that as the elevation angle is changed, the silhouette of the object just rotates in the projection plane and thus the elevation bias error, $\theta_{\rm e}$, remains constant for certain given values of the azimuth angle ψ , the roll angle ϕ and the distance B along the optical axis. Since the first order effect on the silhouette, when moving the object along the optical axis is just a change in size, we can say that the elevation bias error is nearly invariant with the distance B along the optical axis.

3.8 Sample Set Construction

In sections 3.5 and 3.6, we have derived five different functions of moments of the planar pattern, which are invariant with the elevation angle 6 and the distance B along the optical axis of the object to be identified. Thus, these five functions of moments can be used to provide a parametric representation of the silhouette of the object for given values of the azimuth and roll angles in a five-dimensional vector space. The moment functions M₂, M₃, M₄, M₅ and M₆ of Eqs. (3-23) through (3-27) are of different orders. Invariant moment functions of the same order should be used for the parametric representation of the silhouette in order to give equal weight or the same importance to each parameter used in the recognition procedure. Therefore, let

$$\rho_1 = M_2'$$
 (3-30)

$$\rho_2 = (M_3)^{4/6}$$
 (3-31)

$$\rho_3 = (M_4)^{4/6}$$
 (3-32)

$$\rho_4 = (M_5)^{4/12}$$
 (3-33)

$$\rho_5 = (M_6)^{4/8}$$
 (3-34)

and then, the vector $\vec{\rho} = (\rho_1, \rho_2, \rho_3, \rho_4, \rho_5)$ represents the given silhouette in a five dimensional vector space.

A simulation program for obtaining the silhouette of a given object for any translation and orientation [26] is used here for construction of the sample set. The possible range of variations of the azimuth angle ψ and the roll angle ϕ are discretized; and then for all

of the different combinations of these discretized values of the two angles with the values of A and C taken as zero, silhouettes are generated from which the parameters ρ_1 , ρ_2 , ρ_3 , ρ_4 , ρ_5 , the constant RK, and the elevation bias error θ_e are computed. Thus a sample set is constructed for a certain object and then repeated the same way for the other objects to be identified.

3.9 Nearest Neighbor Rule for the Identification and Estimation of the Parameters

Let the vector $\vec{\rho}_i$ represent the ith pattern in a five dimensional vector space from the sample set $(\vec{\rho}_1, n_1), \ldots, (\vec{\rho}_n, n_n)$ where the n_i 's take values in the set $\{1, 2, \ldots, K\}$. Each n_i is considered to be the index of the category to which the ith individual belongs, and each $\vec{\rho}_i$ is the outcome o' the set of measurements made upon that individual pattern. For brevity, we can say " $\vec{\rho}_i$ belongs to n_i " when we precisely mean that the ith individual, upon which measurements $\vec{\rho}_i$ have been made, belongs to category n_i .

A new pair $(\stackrel{\rightarrow}{\rho}, n)$ is given, where only the measurement $\stackrel{\rightarrow}{\rho}$ is made, and it is desired to estimate n by utilizing the information contained in the sample set of correctly classified vectors. We shall call

$$\vec{\rho}' \in \{\vec{\rho}_1, \vec{\rho}_2, \dots, \vec{\rho}_n\}$$

a nearest neighbor [29] to p if

min
$$d(\hat{o}_1, \hat{o}) = d(\hat{o}_1, \hat{o}) = 1,2, ...n.$$
 (3-35)

The unknown input $\vec{\phi}$, by the nearest neighbor rule, belongs to the category or the class n' of its nearest neighbor $\vec{\phi}'$ defined in Eq. (3-35). A mistake is made when $n' \neq n$. The nearest neighbor rule described here utilizes only the classification of the nearest neighbor. The remaining n-1 classifications are ignored.

The computations involved in this approach are fairly simple.

An alternative approach using linear separatibility of the sample set into different classes could possibly be used for the identification, but then the computations involved would be more complex and difficult.

3.10 Summary

In this chapter we first considered the mathematical representation of the object to be identified and of the optical system. Some functions of moments which are invariant with the elevation angle θ and the distance B along the optical axis were used to characterize the silhouette for the given values of the azimuth angle ψ and the roll angle ϕ . A procedure was then described to form the sample set; then using this sample set a nearest neighbor rule useful for the identification and the estimation of the parameters of the unknown object was discussed.

CHAPTER IV

COMPUTATIONAL RESULTS

4.1 Introduction

Wire Frame structure representation of three different aircraft, a F-4B Phantom II, a Mirage IIIC, and a MIG 21 is presented in this chapter. The moment functions which are invariant with the elevation angle and the distance along the optical axis, derived in Chapter III, are then analyzed. Using the parametric representation of the sil-houettes generated, the construction of the sample set for the three aircraft considered is shown. The results obtained by the application of the nearest neighbor rule described in Chapter III for the identification and estimation of parameters are presented later in this chapter. The effect of noise on identification and estimation is also studied.

4.2 Wire Frame Structure Representation

Prototype models of scale 1:72 are used for the purpose of obtaining the wire frame structure representation of the three different aircraft considered. A number of points called nodes are selected on the body of the prototype to represent the three dimensional objects, or the aircraft, in the present case. The number of nodes required and their positions on the body of the prototype for a complete and fair representation of the three dimensional object depends on the object's

complexity. It is obvious that the number of nodes necessary to represent a curved surface would be more than that necessary to represent a planar surface. The computation time required to generate the silhouette for a certain given translation and rotation increases more than linearly with the number of nodes selected.

The coordinates of the 79 nodes selected on the Phantom F-4B aircraft, with respect to the center of gravity of the aircraft, appear in Table I. The connection matrix for these nodes selected is given in Table II.

The trailing zeroes in the rows of the connection matrix of Table II show that no more nodes are connected to the node representing that row. For example, node 77 is only connected to the nodes 76, 79, 1 and 2.

Similar measurements were made for nodes selected for the other two aircraft. The body of the Mirage is less complex in shape than those of the Phantom and MIG aircraft, and therefore it is only necessary to select 59 nodes for the Mirage. The coordinates of the nodes and their connection matrix for the Mirage and MIG aircraft appear below in Tables III through VI.

4.3 Generation of Data Points

It is desired to represent the given silhouette of a certain object by some finite number of points called data points. These data points are used for the calculation of moments for the given silhouette. The most realistic situation about the existence of these data points is perhaps to have them uniformly distributed along the silhouette or the boundary of the optical image. The subroutine that generated these data points is called DATA.

Let UVLE be the distance between any two adjacent data points on the silhouette or the boundary. The number of data points generated for a given silhouette is inversely proportional to the distance UVLE; and therefore as the distance UVLE is decreased, the computation time required for the moment calculations is increased. However, by decreasing the distance UVLE, one can obtain a more faithful discrete representation of the given continuous silhouette. A compromise for the value of UVLE, on the basis of the computation time and the accuracy desired, is made.

For a certain given silhouette, the variation in the values of the parameter ρ_3 of Eq. (3-32) with the distance UVLE is shown in Figure 4.1. The parameter ρ_3 varies considerably for values of UVLE greater than 0.0003 inch and remains nearly constant for values of UVLE less than 0.0003 inch. This shows that for values of UVLE for which any of the parameters ρ_1 , ρ_2 , ρ_3 , ρ_4 or ρ_5 remain nearly constant, we have a comparatively more exact and fair representation of the given continuous silhouette. A compromise, on the basis of the computer core available, the computation time and the accuracy desired, is made for UVLE equal to 0.0002 inch.

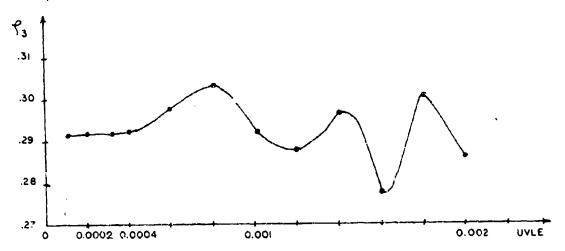

Figure 4.1 Variation of the Parameter og with UVLE

4.4 Moment Invariance with the Angle of Elevation

It was shown in Chapter III that the vector $\vec{\rho} = (\rho_1, \rho_2, \rho_3)$, ρ_4, ρ_5 , where the parameters $\rho_1, \rho_2, \rho_3, \rho_4$ and ρ_5 are functions of moments which are invariant with the elevation angle θ and the distance B along the optical axis, characterizes a silhouette with given azimuth and roll angles. The invariance of one of these five parameters, ρ_1 , with the elevation angle is shown in Table VII. Similar results hold for the other parameters also.

90.0	C.8158	0.8180	0.8180
<u> </u>			· · · · · · · · · · · · · · · · · · ·

It is seen from Table VII that the value of the parameter ρ_1 does not vary with the elevation angle θ for the case when the center of gravity of the object to be identified lies on the optical axis. For the other two cases where the center of gravity is off the optical axis,

parameter o₁. For the present case, it is reasonable to assume the maximum value of the off-axis distances A and C to be about 30 ft. only, as for values greater than this the aircraft, with our present considerations, will not be completely in view. This is shown in Figure 4.2 where the silhouette is generated for the off-axis distances A and C equal to 25 ft., and the optical axis distance B equal to 10,000 ft. This maximum value for the off-axis distances A and C will obviously decrease when smaller optical axis distances are considered.

4.5 Moment Invariance with Distance Along the Optical Axis

It was stated in the last chapter that the radius of gyration of the optical image or the silhouette is inversely proportional to the distance of the object along the optical axis, and hence the product RK of the radius of gyration and the distance along the optical axis remains constant. This is shown to be valid from the computational results shown in Table VIII.

The fact that the product RK remains nearly invariant with the distance along the optical axis was used in Chapter III to normalize some of the moment functions to obtain their invariance in relation to the distance along the optical axis. The variation of one of the parameters ρ_A with the distance B is shown in Table IX.

4.6 Sample Set Construction

A simulation program which appears in Appendix I is used to generate the silhouette of an object, given its three translational and three rotational parameters. The possible range of variation of the

azimuth angle ψ and the roll angle φ are 0 to 360 degrees. But because of the symmetry of the aircraft about their major axis or the x-axis of the coordinate system fixed to the center of gravity, the silhouettes for the four roll angles φ , 180 - φ , 180 + φ and 360 - φ will be almost similar. Thus we will expect the parameters ρ_1 , ρ_2 , ρ_3 , ρ_4 and ρ_5 to have nearly the same values for all the four angles mentioned above; and therefore the same vector $\overrightarrow{\varphi} = (\rho_1, \rho_2, \rho_3, \rho_4, \rho_5)$ will represent the four silhouettes for these roll angles, with the same azimuth angles. This is shown in the Figure 4.3.

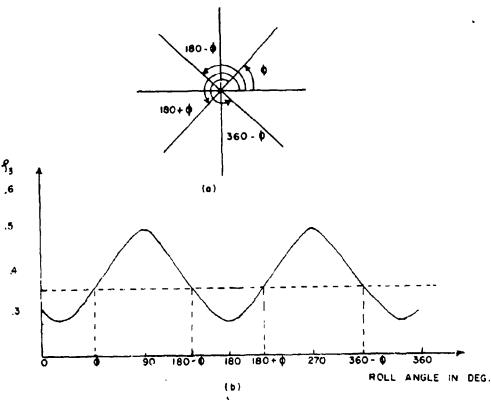

Figure 4.3 Representation of the Four Different Roll Angles having similar Silhouettes

The same considerations apply to the azimuth angle also. Making use of these symmetric properties of the roll and azimuth angles, we may consider the variations of ϕ and ψ from 0 to 90 degrees only. The range of variations of the azimuth and roll angles are discretized at an interval of 5 degrees each; and then for all of the different combinations of these discretized values of the two angles with A and C taken as zero, silhouettes are generated from which the parameters ρ_1 , ρ_2 , ρ_3 , ρ_4 , ρ_5 , the constant RK, and the elevation bias error θ_e are computed. Thus the whole sample set consisting of 361 pattern vectors for each aircraft is constructed. Tables X and XI give the sample set for the Phantom are Mirage aircraft respectively. The variations for ψ and φ in these tables appear in steps of 15 degrees, but these tables were computed in steps of 5 degree variations.

4.7 Identification and Estimation of the Parameters

The Nearest Neighbor Rule described in Chapter III is used for the identification and estimation of the three translational and the three rotational parameters. The sample set $(\vec{\rho}_1, \eta_1), (\vec{\rho}_2, \eta_2)$... $(\vec{\rho}_n, \eta_n)$ is stored in the computer; and then for an unknown pattern vector $\vec{\rho}$, its nearest neighbor defined in Eq. (3-35) is searched. This is done by using the subroutine ESTM, given in Appendix I.

4.7.1 Identification of the Unknown Object

Let the nearest neighbor of the unknown pattern vector \vec{p} be (\vec{p}', n') . We may therefore say that \vec{p} belongs to n'. The information contained in n' is the class of the object, the azimuth and roll angles,

the constant RK and the elevation bias error $9_{\rm e}$. Thus the class of the object, or the aircraft type in our present case, obtained from n' does the required identification. We define a new term certainty of identification as

$$CER = D_2/(D_1 + D_2)$$
 (4-1)

where

- D₁ = distance of unknown pattern vector from its nearest neighbor of the class identified
- D₂ = distance of unknown pattern vector from its nearest neighbor of the other class.

4.7.2 Estimation of the Translational and Rotational Parameters

Information about the azimuth and roll angles, the constant RK and the elevation bias error θ_e is obtained from n', and is used to estimate the six parameters.

The values of the azimuth and roll angles obtained from η' are only approximate estimates for the two angles. A technique using linear interpolation is then used to generate 102 new pattern vectors of some known azimuth and roll angles around the nearest neighbor (ρ', η') . Let ψ_E and φ_E be the azimuth and roll angles obtained from η' . The closest 8 neighbors of ρ' from the sample set are the pattern vectors with the azimuth and roll angles as shown below in Figure 4.4. Using these 8 neighbors of ρ' , we can generate 102 new pattern vectors for

æ.,

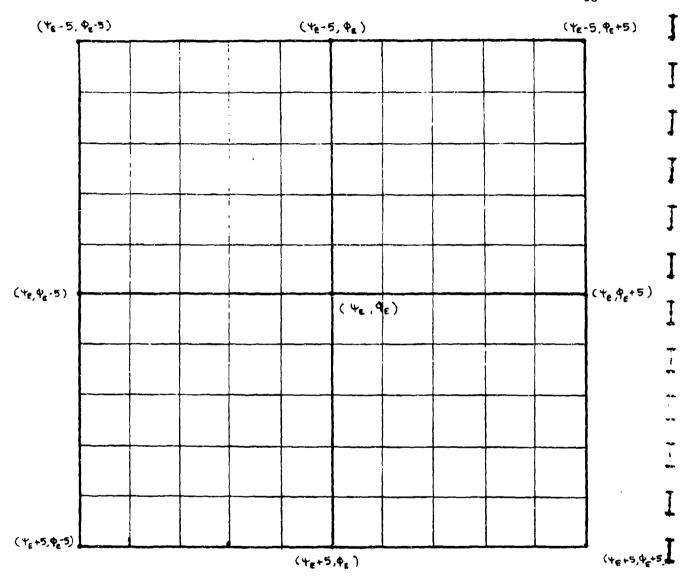

Figure 4.4 Values of ψ and φ for New Pattern Vectors Generated by Interpolations

the variation in steps of 1 degree each in the values of the azimuth and roll angles. This is accomplished by interpolating the values of a_1 , a_2 , a_3 , a_4 and a_5 separately for all the new positions shown in Figure 4.3 by using the above mentioned 8 neighbors. This is done by the INTP subroutine. The Nearest Neighbor Rule is then used again to find the closest match for the unknown vector \vec{b} from the newly generated pattern vectors. Thus from this closest match found, we extract estimates for the azimuth and roll angles accurate up to 1 degree in noiseless cases.

The estimate for the distance of the unknown object along the optical axis is as shown below:

$$B_E = RK_E/r (4-2)$$

where $RK_{\overline{E}}$ is the value of the constant RK obtained from n', and r is the radius of gyration of the silhouette of the unknown object to be identified.

The inclination e_m of the major axis of the ellipse fitted to the pattern can be found from Eq. (3-28), which appears below

$$\tan 2\theta_m = -2u_{11}/(u_{20} - u_{02})$$

and,

$$u_{20}' \rightarrow u_{02}'$$
 . (4-3)

The elevation bias error θ_e for the unknown pattern vector is obtained from n', and therefore the estimate θ_E for the elevation angle is given by

$$\theta_{\mathbf{E}} = \theta_{\mathbf{m}} + \theta_{\mathbf{e}} \tag{4--4}$$

For the purpose of estimating the values of the off-axis distances A and C, we assume that the center of gravity of the unknown object is projected very near the centroid of its silhouette in the image plane. Therefore, from Eqs. (3-1) and (3-2), we have,

$$A_E = X_{CG} = U_{CG} \cdot (B_E + f)/f$$
 (4-5)

$$C_E = Y_{CG} = V_{CG} \cdot (B_E + f)/f$$
 (4-6)

where (U_{CG}, V_{CG}) is the centroid of the silhouette, B_E is the estimate for the distance along the optical axis and f is the focal length of the optical system. Thus we have been able to estimate the three translational and the three rotational parameters of the unknown object.

4.7.3 Results of Identification and Estimation in the Absence of Noise

Several silhouettes were generated with known reference translational and rotational parameters, and the pattern vector $\vec{\rho} = (\rho_1, \rho_2, \rho_3, \rho_4, \rho_5)$ was computed for each of the silhouettes. With the help of these pattern vectors, the identification and estimation was achieved. Results of some of the identifications and estimations appear in Table XII.

It is seen from the results of Table XII, that the accuracy of the estimation of parameters is as shown below in Table XIII.

TABLE 13
ACCURACY OF ESTIMATION OF THE PARAMETERS

Parameters	Accuracy
Azimuth Angle	±1 degree
Roll Angle	±1 degree
Elevation Angle	±0.1 degree
Distance B	2 percent
Distance A	±2.0 feet
Distance C	±2.0 feet

It is to be noted from Table XII that the certainty of identification was always found to be very high, and from this we can infer that the clusters formed by the pattern vectors of each aircraft are nonoverlapping or separate.

4.7.4 Results of Identification and Estimation in the Presence of Noise

In a realistic system one would expect that the measurement points would not exactly overlay the boundary of the pattern from which they came. This error may be due to several different reasons. For instance, if the field of view has been slightly clouded over, or defocused, then the boundary of the pattern is no longer precise and the exact coordinates of points lying on the boundary can only be estimated. Even if the field of view is clear there is still the

The trap that the Table II

6b. Estimated Parameters	Phantom	-0.5	-0.5	7000	22	3	-12.0	100

possibility that the electronic equipment associated with the ortical system can commit errors, he they internal or transmission errors. Furthermore, there is always the quantization error associated with analog to digital conversion. All of these errors may be considered as forms of noise.

A simulated silhouette for certain reference parameters for the Mirage appears in Figure 4.5 with a certain amount of noise added to the data points. The identification and estimation for this simulated silhouette is shown below in Table XIV.

TABLE 14

IDENTIFICATION AND ESTIMATION IN THE PRESENCE OF NOISE (Aircraft Considered: Mirage, Aircraft was Identified to be Mirage)

Parameters	Roterence Value	Estimated Value
Noise	3.4%	
A	8.0 feet	7.7 feet
С	12.0 feet	12.0 feet
В	5500 feec	5496 feet
ψ	3°	υ °
φ [13°	14°
е	-40.0°	-40.1°
CER		100%

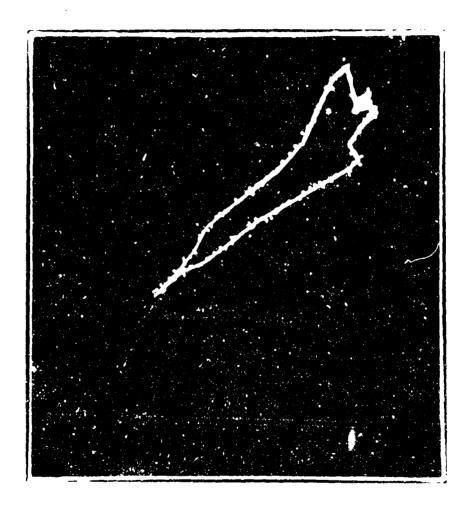

Figure 4.5 Perspective View of Mirage with A = 8 ft., B = 5550 ft., C = 12 ft., ψ = 3°, ϕ = 13°, 6 = -40.9°, and with a noise of 3.4% added to the data points

Simulated silhouettes for certain reference parameters for the Phantom aircraft with different amounts of noise added appear in Figure 4.6 through 4.10. The identification and estimation for all these simulated silhouettes appear in Table 15. It should again be noted that the identification of the aircraft type was done correctly even in the presence of noise, and therefore showing the presence of nonoverlapping clusters formed by the pattern vectors of each aircraft.

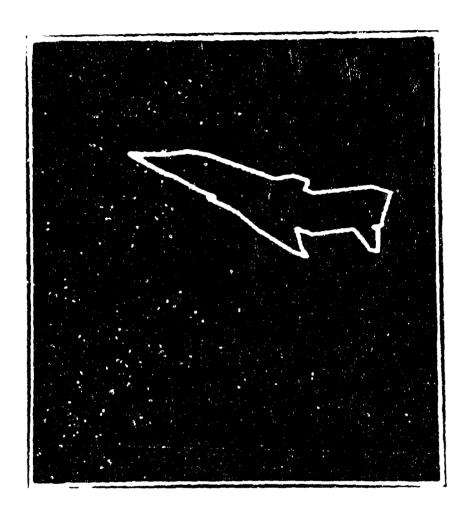

Figure 4.6 Perspective View of Phantom with A = 10 ft., B = 7500 ft., C = 12 ft., ψ = 7°, ϕ = 22°, θ = 18°, and with a noise of 0.0% added to the data points

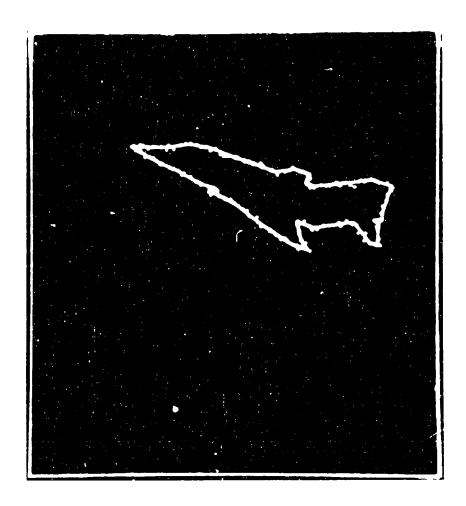

Figure 4.7 Perspective View of Phantom with A = 10 ft., B = 7500 ft., C = 12 ft., ψ = 7°, ϕ = 22°, θ = 18°, and with a noise of 2.2% added to the data points

₹.P2.

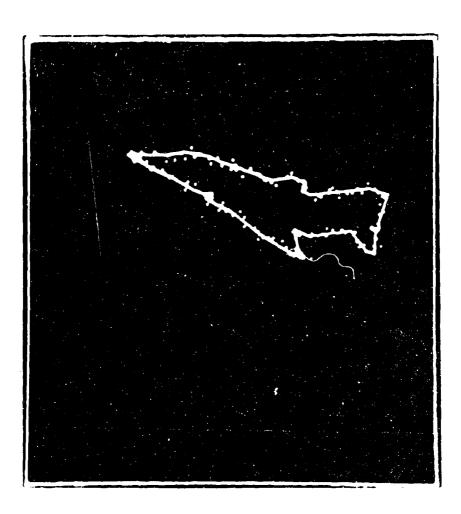

Figure 4.8 Perspective View of Phantom with A = 10 ft., B = 7500 ft., C = 12 ft., ψ = 7°, ϕ = 22°, θ = 18°, and with a noise of 4.8% added to the data points

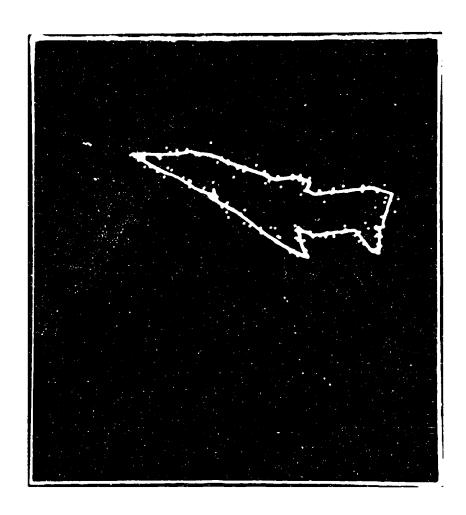

Figure 4.9 Perspective View of Phantom with A = 10 fc., B = 7500 ft., C = 12 ft., ψ = 7°, ϕ = 22°, θ = 18°, and with a noise of 7.6% added to the data noints

τne.

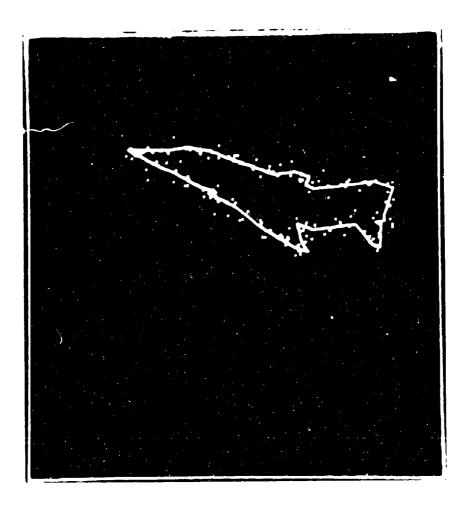

Figure 4.10 Perspective View of Phantom with A = 10 ft., B = 7500 ft., C = 12 ft., ψ = 7°, ϕ = 22°, θ = 18°, and with a noise of 10.0% added to the data points

TABLE 15 IDENTIFICATION AND ESTIMATION IN THE PRESENCE OF NOISE AIRCRAFT CONSIDERED: PHANTOM

REFERENCE PARAMETERS: A = 10 FEET, B = 7500 FEET, C = 12 FEET, ψ = 7°, ϕ = 22°, θ = 18°

CHAPTER V

SUMMARY AND CONCLUSIONS

This thesis is aimed at a solution to the problem of real time identification of three dimensional objects from their optical images. The approach taken here relies upon the invariant functions of moments which are used for the construction of the sample set.

The method of moments appears to work quite well for the identification of aircraft from their optical images. The results obtained in Chapter IV show that the performance of the method of moments for aircraft identification is comparable to that of a human photo interpreter, and it is roughly equivalent to or better than heuristic techniques. Failure to surpass the performance of a human is not always a serious liability, however. In many situations, automation is required, even if the resulting performance is not as good as that of a human. When automation is required, the method of moments is quite possibly the best method, because it is easier to implement than the other heuristic techniques, which require point-by-point image analysis.

So far as is known to the author, no alternative image processing technique exists with a capability of real time identification and estimation of parameters of three dimensional objects. The algorithm developed in this research has the potential of reaching real time identification when a special purpose computer with multiprocessing

capabilities is used to do the requisite searches. An associative memory could also be used to store the sample set in order to decrease the identification time required.

While all of the results contained in this thesis relate to three different aircraft that were considered, it appears that this approach would be applicable for a larger number of objects as well. Further work in the following areas could lead to better accuracy in estimation of the parameters and in reduction of the limitations of the present method:

- (1) An optimum distance function for use in the Nearest Neighbor Rule described in Chapter III.
- (2) Linear separatibility for dividing the sample set into different regions or classes.
- (3) Syntactic analysis to resolve the ambiguities between certain roll angles and azimuth angles such as between ϕ and $-\phi$, ψ and $-\psi$ or the nose and the tail of the aircraft.
- (4) Design of a system to gather data, for use in moment calculations, from the optical image of an object.
